

Homework

1. Does sensor fusion always reduce variance?

In class we discussed the optimal linear fusion of two, one-dimensional, Gaussian information sources is

$$\hat{x} = \frac{r}{q+r}x_p + \frac{q}{q+r}z$$

where $x_p \sim \mathcal{N}(0, q)$ and $z \sim \mathcal{N}(0, r)$. Prove

$$p \leq \min\{q, r\}$$

where p is the variance of the estimate.

2. Does a Kalman Filter always reduce variance?

What is the relationship between the process noise q and the measurement noise r such that $p[t]$ is marginally stable in a Kalman Filter (Hint: marginal stability implies $0 < \lim_{t \rightarrow \infty} p[t] < \infty$)? How is this different from Question 1?

3. Under what conditions is a Kalman Filter optimal?

- List at least 6 assumptions made when using a Kalman Filter
- How are the assumptions from (a) relaxed/changed for a EKF? UKF?

4. Creating an Extended Kalman Filter

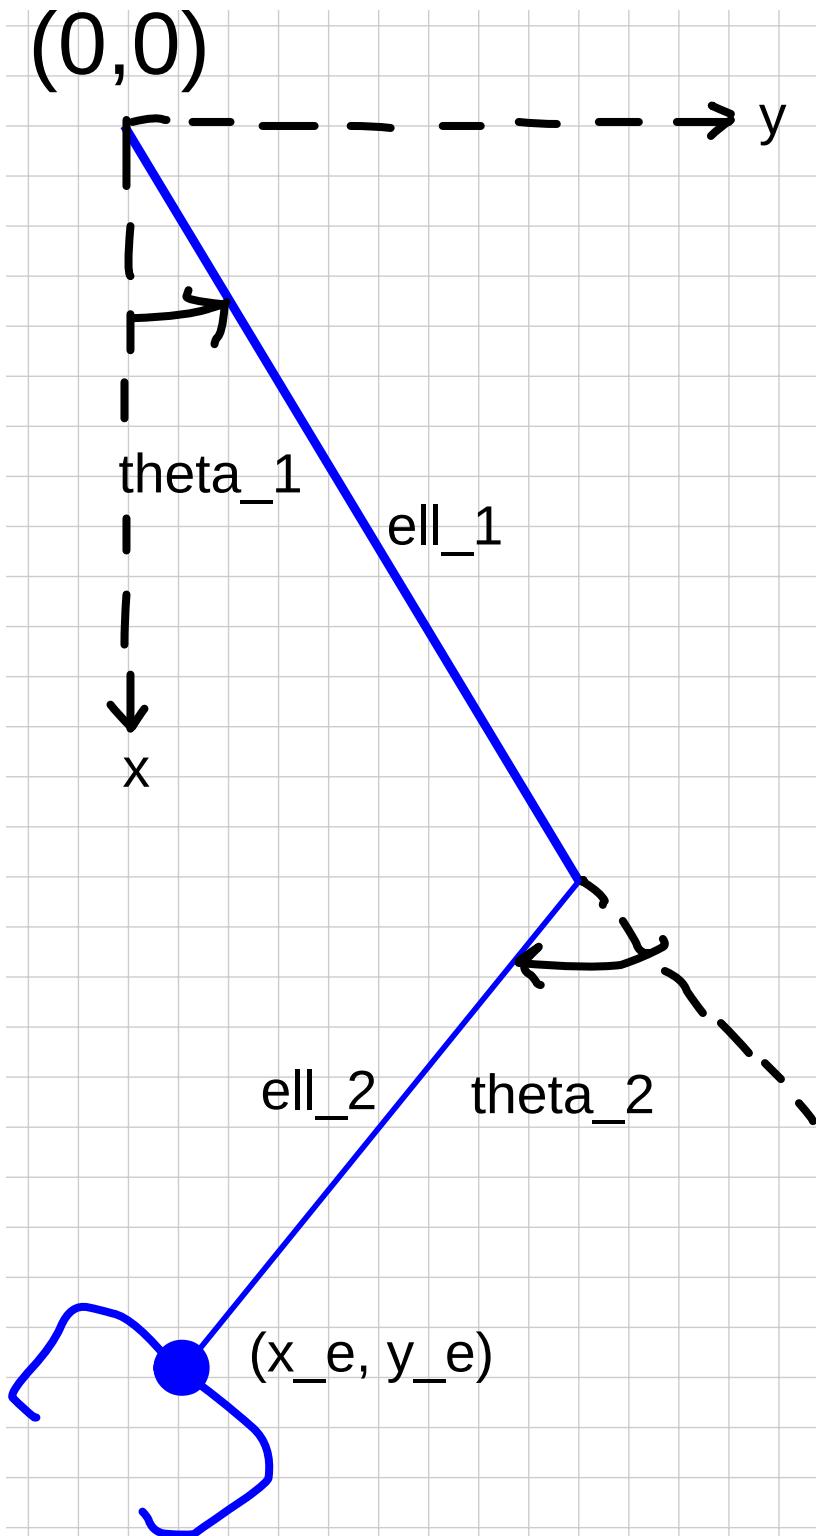

Design a discrete-time EKF to estimate the position of a robotic end effector using only measurements of θ_1 and θ_2 (e.g. [Identify \$F_t\$, \$Q_t\$, \$H_t\$, and \$R_t\$](#)). Assume a constant velocity model such that

$$\theta_1[t] = \theta_1[t-1] + \omega_1[t-1]\Delta t + \nu_1$$

and

$$\theta_2[t] = \theta_2[t-1] + \omega_2[t-1]\Delta t + \nu_2$$

where $\nu_1 \sim \mathcal{N}(0, \sigma_{\theta_1}^2)$ and $\nu_2 \sim \mathcal{N}(0, \sigma_{\theta_2}^2)$. Positive angles are clockwise!

- Identify the continuous-time kinematic equations relating joint angles to the end effector position.
- Discretize these equations using [Euler Integration](#) (also known as a first-order Taylor Series approximation).
- Ensure these equations are [Markov](#) (i.e. a state at the next time step only depends on states at the current time step). By now, you should have a system of **6** equations describing the **process**. (Hint: You really only need to find 4 because two are given: $\theta_1[t]$ and $\theta_2[t]$)
- List the states as a large vector \mathbf{x} . The system of equations should be expressed as a function $f : \mathbb{R}^6 \rightarrow \mathbb{R}^6$ that inputs the states and produces the state at the next time step.
- You will now need to repeat steps (a)-(c) to identify the **observation or measurement** equations. These equations should be functions of the states you listed in (d) and return the desired

measurement. These equations should be expressed as a function $h : \mathbb{R}^6 \rightarrow \mathbb{R}^n$ where n is the number of observations.

- A subtle assumption made by an EKF is all states are contained in the real numbers. However, the angles θ_1 and θ_2 wrap. This can cause problems when trying to perform measurement updates. For example, if my measurement is 0 and my current estimate is 359, the difference is 359 and not 1 (this differencing occurs when calculating the **residual**). *Be sure to select the observation equations such that this wrapping error does not occur.* (Hint: $e^{j\theta} = \sin \theta + j \cos \theta$)

f) The equations f and h should not be linear with respect to the states. To linearize them, calculate the Jacobians for both. (Hint:

$$F[i, j] = \frac{\partial f_i(\mathbf{x})}{\partial x_j}$$

where i and j denote the row and column of the Jacobian, respectively.)

g) Assuming ν_1 and ν_2 are uncorrelated (i.e. not related to each other), create the **process noise** matrix Q and the **observation noise** matrix R (Refer [here](#) for how these matrices are used). Also assume ν_1 and ν_2 are the only process noise sources and all observations have uncorrelated, Gaussian, zero-mean noise with $\sigma^2 = 0.1$.
